

1 Thesis Proposal

2 Christophe Rouleau-Desrochers

3 November 6, 2025

4 **1 Introduction**

5 **1.1 Climate change impacts on tree phenology**

6 An important body of research from the past decades have shown convincing evidence that human activity
7 are increasingly affecting many worldwide environmental processes Ceballos *et al.* (2017); Intergovernmental
8 Panel On Climate Change (Ipcc) (2023); Laurance (2007); Parmesan & Yohe (2003). This can be through
9 land use change and destruction, pollution, invasive species, ressource overexploitation and climate change
10 Driscoll *et al.* (2018); Parmesan *et al.* (1999); Wu (2013). That alone raises major concern and actions
11 have been deployed to mitigate these impacts, with varying success (e.g. Campbell *et al.* (2014)). Even
12 though immediate actions can have positive impacts and potentially reduce some threats to biodiversity,
13 reversing 150 years of human induced greenhouse gas emissions is harder. These emissions have already
14 affected Earth's climate and they are projected to continue affecting Earth's climate centuries. While there
15 is a scientific consensus that observed climate change is human-caused Change (2014); Lynas *et al.* (2021);
16 Oreskes (2004), the magnitude and the extent of the consequences that a warming climate will have on
17 biological processes are still debatable Huey *et al.* (2012). Historically, the first case of attribution of a
18 biological change to climate change was about poleward shifts of european butterflies in Europe in response
19 to regional warming Parmesan *et al.* (1999).

20 **1.1.2. Trends of spring and autumn phenological events and their drivers** The most frequently
21 observed biological impact of climate change over the past decades are major changes on spring and autumn
22 phenology — the timing of recurring life history events Parmesan & Yohe (2003); Cleland *et al.* (2007); Lieth
23 *et al.* (1974); Woolway *et al.* (2021); Menzel *et al.* (2006). Understanding the consequences of these shifts on
24 ecosystems requires understanding how much the growing season has changed Duputié *et al.* (2015). Spring
25 phenological events (e.g. budburst and leafout) have been advancing from 0.5 Wolfe *et al.* (2005) to 4.2
26 days/decade Chmielewski & Rötzer (2001); Fu *et al.* (2014) and are mainly driven by temperature Chuine
27 (2010); Cleland *et al.* (2007); Peñuelas & Filella (2001). In contrast, autumn phenology (e.g. budset and leaf
28 colouring) is delayed, though to a much lesser extent than spring Gallinat *et al.* (2015); Jeong & Medvigy
29 (2014). The drivers regulating autumn phenology are far less understood than those of spring for many
30 reasons. First, autumn phenology has attracted much less attention compared to spring Piao *et al.* (2019).
31 Second, the data is often much noisier, since meteorological conditions in the fall can drastically influence
32 phenological phenomena. To illustrate this, trees going through leaf senescence are subjected to a gradual leaf
33 abscission that follows nutrient reabsorption, and the leaves within the same individual might be at different
34 senescence stage, but a strong wind spell may trigger leaf drop for all leaves, thus affecting the temporal
35 resolution of these data Wu *et al.* (2024). However, there is a general belief that autumn phenophases are
36 driven by shortening photoperiod and colder temperatures Cooke *et al.* (2012); Flynn & Wolkovich (2018);
37 Körner & Basler (2010); Delpierre *et al.* (2016). Different hypothesis are proposed to explain delayed au-
38 tumn phenophases. First, warmer autumn temperature may extend the activity of photosynthetic enzymes
39 which could be maintained at a higher level. Thus, the degradation rate of chlorophyll would decrease and
40 timing of senescence would be delayed Yan *et al.* (2021). Second, summer droughts could make trees pause
41 their activity schedule and delay senescence to increase carbon assimilation Dox *et al.* (2022). Third, there
42 could be an antagonistic effect of warming and brightening—caused by reductions in atmospheric pollution
43 and cloud cover Sanchez-Lorenzo *et al.* (2015)—on leaf senescence Wu *et al.* (2021). Brightening accelerates
44 the leaf senescence processes and reduces the temperature sensitivity during that period, counteracting the

45 expected warming-induced delays in leaf senescence. The photo-protection and sink limitation hypothesis
46 provide plausible explanations for the negative effect of radiation on leaf senescence and the declining effect
47 of temperature sensitivity of leaf senescence in response to brightening Wu *et al.* (2021); Zani *et al.* (2020).

48
49 **1.1.3. Mis-leading evidence of declining sensitivity to warming** While we have convincing proof
50 that spring events advanced in the past decades, there is evidence that this might decelerate because of
51 declining sensitivity to warming Fu *et al.* (2015); Meng *et al.* (2020). The proposed mechanism is through
52 the action of warmer winters on tree dormancy. In the fall, trees in boreal and temperate forests slowly
53 enter dormancy which is initiated with budset. During this phases, cold hardiness increases which prepares
54 the trees for the upcoming cold temperatures and prevents tissue damage. Then, the trees enter dormancy,
55 during which a certain duration of chilling temperatures—with some interaction with photoperiod for some
56 species—is necessary for the trees to be ready to accumulate forcing Vitasse *et al.* (2014). In the late winter
57 and early spring, they go through two forms of deacclimation before budburst Vitasse *et al.* (2014). When
58 deacclimation is reached, a certain amount of heat (forcing) is required to initiate budburst Fu *et al.* (2015).
59 The argument of declining sensitivity appears here: heat requirement is met sooner in warm springs, but
60 it's also negatively correlated with chilling Fu *et al.* (2015, 2013); Laube *et al.* (2014). However, it is this
61 interaction between chilling and forcing requirements that determines the timing of leaf unfolding. In other
62 words, a decrease in chilling accumulation is proposed to explain the observed weaker spring temperature
63 sensitivities, where spring forcing looses of its relative importance Fu *et al.* (2015); Meng *et al.* (2020);
64 Wolkovich *et al.* (2021). However, a meta-analysis compiling 72 studies of 203 species suggests that declining
65 sensitivities observed in Europe may be a statistical artifact of how these responses are calculated, thus
66 casting doubt on this proposed trend Ettinger *et al.* (2020). This statistical artifact may be caused by using
67 linear models for calculating non-linear processes Wolkovich *et al.* (2021).

68 **1.1.2. Mechanisms that could limit growth despite having a longer growing season** Plants
69 seasonal activity has internal and external controls, both determined by environmental conditions. Internal
70 controls operate via autonomous clocks, activating genes and releasing hormones which often rely on chilling
71 and/or photoperiod. The external controls, often referred to as forcing, act directly on the developmental
72 rate, meristem activity, tissue differentiation and metabolism Körner *et al.* (2023). These controls have often
73 been overlooked, but are nevertheless critical to our understanding of plant's capacity to adjust their activi-
74 ty schedule in response to changing conditions Chuine & Régnière (2017). In light of this, I hypothesize
75 two possible drivers that could explain why a longer growing season might not lead to increased growth:
76 external (environmental) Kolář *et al.* (2016) and internal (via physiological constraints) Zohner *et al.* (2023)
77 constraints to growth.

78
79 *1.1.2.1. External constraints* The complex nature of climate change makes predicting the external limits
80 to growth hard to quantify at the individual level, as these drivers affect communities as a whole. How-
81 ever, drought, spring frost and heat waves are commonly mentioned as the main extreme events that could
82 limit tree growth under climate change Tyree & Zimmermann (2002); Choat *et al.* (2018); Li *et al.* (2023);
83 Trenberth *et al.* (2014); Change (2014); Chiang *et al.* (2021); Polgar & Primack (2011); Reinmann *et al.*
84 (2023). Their respective mechanisms, global trend of occurrence, consequences and difference among species
85 are described in Tables 3.1. (Spring frosts), 3.2. (Droughts) and 3.3. (Heat waves).

86
87 *1.1.2.2. Internal constraints* As for the internal constraints to growth, recent hypothesis propose that
88 broadleaf deciduous tree species may be sink-saturated, such that longer growing season with more carbon
89 fixation do not necessarily increase growth Dow *et al.* (2022). This one pathway is directly linked to the
90 internal controls of plant growth, which are under strong genetic control. In addition to height and radial
91 growth varying across species, these growth responses also vary by site Silvestro *et al.* (2023a); Aitken &
92 Bemmels (2016). Populations from higher altitude or latitude grow less under the same conditions than
93 individuals from lower altitude or latitude Way & Montgomery (2015). This is further supported by pheno-
94 logical studies showing that growth stop arrives earlier from populations of higher latitude, demonstrating
95 local adaptation to potentially avoid fall frost, before nutrient uptake has finished Aitken & Bemmels (2016);
96 Vitasse (2013); Way & Montgomery (2015). These trees rely on photoperiod cues for setting buds (stopping
97 height growth) Way & Montgomery (2015); Soolanayakanahally *et al.* (2013).

98 Growth seasonality has huge consequences on overall annual growth and so are the environmental con-

99 ditions during these periods. For instance, warming spring temperatures seem to positively affect growth,
100 but recent evidence suggest a shift in this net positive effect near the summer solstice. Indeed Zohner *et al.*
101 (2023) found that warmer temperatures before the solstice advanced the onset of senescence, but it slowed
102 the progression of leaf colouring when temperatures postsolstice were warmer. This further reinforces the
103 importance of understanding how the timing of warmer conditions affect tree species.

104
105 **1.1.3. How these shifts translate into effects on trees/forests are not clear - Pros and cons**
106 **of early/late start/end of season (figure?)** Shifts in spring and autumn phenology support a long-lasting
107 and intuitive assumption that earlier spring and delayed autumn events lead to longer seasons—and thus
108 increased growth Keenan *et al.* (2014); Stridbeck *et al.* (2022). However, research from the past three years
109 has cast doubt on this hypothesis Dow *et al.* (2022); Green & Keenan (2022); Silvestro *et al.* (2023b). For
110 instance, Dow *et al.* (2022) showed that despite an earlier growth onset, neither growth rate nor overall annual
111 increment was increased by longer seasons. This could substantially affect carbon-cycle model projections
112 and thus feedbacks to future climate Richardson *et al.* (2013); Swidrak *et al.* (2013).

113 Understanding these findings requires answering why trees do not grow more despite longer growing
114 seasons. While carbon allocation to above ground biomass is one of the largest carbon sink, how this car-
115 bon is allocated into wood is poorly understood. Indeed, the linear relationship assumption between wood
116 growth and carbon assimilation is not well supported mechanistically and represents an important limita-
117 tion of vegetation models Cabon *et al.* (2022). Net primary production represents the difference between
118 photosynthesis and plant respiration, but this commonly used metric completely omits the representation
119 of growth processes. This is perhaps because of a long-lasting paradigm of source-limited photosynthesis.
120 This has now since then been debunked with carbon fertilization experiments, supporting evidence that
121 direct environmental constraints on growth may be stronger than those on photosynthesis Friend *et al.*
122 (2019); Parent *et al.* (2010). This opens up a new, poorly tested, temperature sensitivity between cambial
123 activity and photosynthesis. Growing evidence suggest that cambial activity may be more sensitive than
124 photosynthesis to a range of environmental conditions such as: water and nutrient availability, and temper-
125 ature Cabon *et al.* (2022, 2020); Muller *et al.* (2011); Peters *et al.* (2021). This demonstrates that carbon
126 projection models that heavily rely on vegetation alone may mislead the amount of carbon sequestered in
127 our forests.

128 **1.1.4. Growing season shifts and consequences on forest ecosystems and services** Spring and
129 fall phenological events are shifting with debatable consequences on tree growth. The sensitivity of cambial
130 activity to water, temperature and nutrients have the potential to have far-reaching consequences given the
131 hard-to-predict nature of future climate change, where any of these variables could vary from low to high
132 amplitude Almagro *et al.* (2025); Cabon *et al.* (2022). This expected asymmetry of future environmental
133 changes makes understanding the internal and external limits to growth critical. Especially, the capacity
134 to tease apart different biomes—as for example boreal vs tropical forests are expected to react differently
135 (REF)—is critical and empirical data coming from experiments, but also from observations are paramount
136 to predict the changes of forest carbon offset from human GHG emissions.

137 **1.2 Nature of the problem, and how to address it**

138 **1.2.1. Past phenological trends can help (or not) predict future phenological changes** Observed
139 phenological trends in the last decades cannot be used directly to extrapolate future phenological changes
140 because: (1) the mechanisms guiding them aren't clear and (2) phenological responses of trees to warming
141 are very likely to not be linear Ettinger *et al.* (2020); Fu *et al.* (2013). Indeed, accurate predictions require
142 an in-depth accurate mechanistic understanding of phenophases and their sensitivities to environmental
143 drivers, especially to temperature and photoperiod Fu *et al.* (2013). Therefore, the very foundation of the
144 assumption that longer seasons increase growth may shift with future climate change. The well observed
145 advance in spring phenology may slow down, and delayed fall phenology may shift towards earlier leaf
146 senescence (through summer drought induced growth cessation).

147 **1.2.2. The assumption that longer seasons lead to increased growth is called into question**
148 Recent work shows an absence of increased growth despite apparent better environmental conditions, thus
149 casting doubt on a simple and intuitive positive relationship between growing season length and growth. This
150 paradox further emphasizes the need to understand better the drivers regulating growth across biomes, but

also how these drivers vary across the species within these biomes. Phenology vary greatly across species (e.g. closely related species tend to budburst at similar time under similar conditions) Wolkovich *et al.* (2014), but so does the relationship between growth and season length which may explain the wide variation of this relationship among communities Buckley & Kingsolver (2012). This highlights a weakness of certain carbon sequestration models that pool species together, which likely overpass important that nuances in the growth responses that could be explained by species differences. This may mislead the future of forest carbon source-sink ratios Green & Keenan (2022); Cabon *et al.* (2022). To better understand how different species respond to warming, different strategies can be used. Experiments are paramount to robustly tease apart the external vs internal drivers (e.g. warmer springs from severe drought later in the season—a common co-occurring reality in natural environments) Morin *et al.* (2010); Primack *et al.* (2015). However, experiments are most often performed on juvenile trees, which are critical for their role in forest regeneration projections, but their responses can hardly be translated to mature trees, which hold the overwhelming carbon biomass proportion of forests Augspurger & Bartlett (2003); Silvestro *et al.* (2023b); Vitasse (2013). Leaf phenology through ground-based observations can provide valuable insights into the growth onset and end of trees that are not suitable for experimental trials since cambial and leaf phenology are closely linked to another. It is to say that knowing when leaves elongate and color, can guide when trees start and stop to grow—fundamental metrics to determine the growing season length. Ground observations has the advantage of providing accurate data of phenological events for specific sites and species. Recently, the widespread use of smart-phones has opened a whole new world of possible phenological through citizen scientists records of data over much larger areas and for a wider range of species Dickinson *et al.* (2012); Hufkens *et al.* (2019); Piao *et al.* (2019). While there are drawbacks of these observations (e.g. non-standard protocols, highly uneven spatial-temporal distribution of these observations), these methods have a huge potential to diversify the phenology data.

1.2.3. Impacts on carbon source-sink projections

1.2.4. Goals of my thesis Using citizen science data, a common garden trial and a large-scale experiment, I aim to better understand how different tree species, at different lifespan stages vary in their growth responses to different season length.

1.3 Complexity of measuring growth and defining growing season length

What is a growing season?

To understand how trees respond to growing season conditions, it is important to define the growing season and growth. First, a problem that arises when one tries to quantify how shifting growing seasons affect growth comes from the definition of the growing season itself. Recently, Körner *et al.* (2023) proposed four definitions addressing this issue: 1. true growing season, based on measurable growth; 2. phenological season, based on visible phenological markers; 3. the productive season, based on primary production and 4. meteorological season, based on environmental conditions.

Here, I will focus on how definition 4., incorporating 4. affects definition 1. as the data collected for this thesis can't address 3. I will use definition 2. to infer a "window of opportunity" during which meteorological conditions (4.) will be used to calculate growing degree days (GDD). I am using the meteorological season within a constrained window, instead of simply using it irrespective of phenology because of the illusion that an absolute increase in GDD over the last decades—is irrespective of the timing of phenophases—also increases growth. Springs are warmer, falls are also sometimes warmer, and summers are warmer which together, increase the number of GDD which may appear to be a reliable proxy for better environmental conditions. However, a fundamental distinction is that there is a "theoretical" and a "real" period at which trees can grow, which is usually defined through the period between budburst and leaf senescence, highlighting the importance of accurate phenology data (REF). FALSE! Check Korner2023.

Models using degree-days are increasing even though they have been used for decades in agriculture (e.g. Gilmore & Rogers (1958); McMaster (1997)). These rely on developmental patterns that are based on temperature dependence to estimate a particular ecological process, in my case, tree-ring width. These models describe a particular response variable as a composite of time and temperature as opposed to time alone. This is a parsimonious method that requires three variables: daily minimum and maximum temperatures and the base temperature at which the process of interest cannot occur (cambial activation in this case) McMaster (1997); Moore & Remais (2014). However, this simplicity comes with a drawback of over-

203 simplifying potentially complex developmental processes in response to varying environmental conditions
204 within a season Bonhomme (2000).

205 *What is growth?*

206 What is growth? Wood formation (xylogenesis) is the major biological process by which carbon is allocated
207 and long-term stored in woody plants. Radial growth is determined by the production of xylem and phloem
208 cells that begins with cambial activation and cell production by cambial initials, following by cell differentia-
209 tion through the following events: 1. Cell enlargement 2. Secondary-wall formation and lignification and
210 3. programmed cell death Etzold *et al.* (2022); Silvestro *et al.* (2025). The rate and duration of these phases
211 lead irreversible radial growth increment usually represented through tree-rings. In these, secondary xylem
212 cells account disproportionately to the number of cells produced because they divide more than phloem cells
213 Plomion *et al.* (2001); Rathgeber *et al.* (2016).

214

215 **1.3.1. Traditional diameter measurements miss the resolution of annual growth increment**

216 Foresters have measured tree diameter and height for decades to infer allometries that could give them a
217 good estimate of how much wood they could collect in a forest (e.g. Meyer (1940); Saunders & Wagner
218 (2008)). The widely used method in forestry is to measure diameter at breast height at punctual time
219 intervals (REF – perhaps saunders?). However these measurements don't provide short-term indicators of
220 growth—especially if taken at multiple years intervals. Therefore, extreme events affecting growth are likely
221 to be missed. In addition, many forest inventories only report diameter measurements and exclude height,
222 because of logistical constraints (Saunders & Wagner (2008)), which reduces biomass estimation quality. This
223 growth data lacks the temporal resolution necessary to properly infer a relationship between growth and
224 environmental conditions.

225 Alongside diameter-height allometric relationship, dendrochronology and its related fields also have long
226 standing traditions in forestry and silviculture. Indeed, tree-ring research was developed in the early 1900s
227 to perform archaeological dating and climate reconstruction Douglass (1928); Pearl *et al.* (2020). Since then,
228 different dendrochronology methods have developed for different purposes, such as the calibration of the
229 terrestrial radiocarbon curve (Helama2023Distinguishin;Reimer2020The) and modelling Earth's past climate
230 and ecological change Pearl *et al.* (2020). More recently, dendroecology—applications of dendrochronological
231 techniques to problems in ecology Fritts & Swetnam (1989)—emerged to answer ecological problems as well
232 as to hindcast (e.g. Bergeron *et al.* (2004)) and forecast ecological processes both at the regional Gazol *et al.*
233 (2018) and global scale Manzanedo & Pederson (2019). Now, these methods can be used to understand more
234 precise growth patterns and their relationship with different environmental factors.

235

236 **1.3.2. Growth increment needs to incorporate wood density in order to evaluate how much 237 structural carbohydrates were stored within a single year.** While tree-ring width are reliable proxies 238 to how much trees grow in each year, at relatively low cost and time, the inclusion of wood density in the 239 analysis may provide data hidden within the tree rings. Indeed Čufar *et al.* (2008) showed that intra- and 240 inter- annual density variations in beech provided more information and at a higher temporal resolution than 241 tree-rings widths alone.

242 In addition to densitometry, increasing number of studies are going beyond traditional ring width by
243 performing analysis using wood anatomy data. For instance, low cost techniques (e.g. "blue intensity"
244 proxy for latewood density Babst *et al.* (2016); Campbell *et al.* (2007) and high resolution imaging Griffin
245 *et al.* (2021); Levanič (2007); Von Arx & Carrer (2014) give rise to a whole new world of possibility regarding
246 the microscopic components of wood anatomical features. Micro-anatomical analyses within tree-rings could
247 be applied to a wide range of applications Pearl *et al.* (2020). The character of annual rings, cell structure,
248 timing of growth and markers for trauma can assist in answering a variety ecological and physiological
249 questions previously unanswered with ring width or density alone, such as how growth is affected by growing
250 season length under anthropogenic forcing.

251 **1.3.3. Asynchrony between primary and secondary growth (internal growth control?)** I argue
252 that internal growth control in trees may shape their growth responses to growing season length and these
253 can be split into two categories: primary and secondary growth synchronicity and growth determinancy.

254 Primary (shoot) and secondary (xylem and phloem formation) growth both contribute to how much
255 carbon is stored in plant tissue, but how much they differ in their responses to environmental drivers is poorly
256 understood. After a dormancy period, trees will start growing, both vertically (primary) and horizontally

(secondary), but there is extreme variation among species as to when each growth starts, for how long it lasts and when it stops. For instance, ring-porous species initiate primary growth early in the season, sometimes, even before budburst (e.g. oaks) Stridbeck *et al.* (2022), whereas xylogenesis in diffuse-porous species are usually more synchronized with budburst. These two examples highlight how more complicated it might be to infer general conclusions as to how growing season shifts may also shift growth, where some species may extend their primary growth, but restrict their secondary growth and vice versa.

In addition to differences in primary and secondary growth synchronicity, the role of internal growth control—often overlooked—may reshape our understanding of growth responses to growing season length Baumgarten *et al.* (2025). In perennial plants, two dichotomous growth strategies are commonly mentioned: determinate and indeterminate growth, though it may appear as species may exist along a gradient of these Baumgarten *et al.* (2025) (REF). Indeterminate growth is usually associated with short-lived and fast growth species where these life-history strategies may give them a competing advantage as tissue growth can be produced quickly in response to changing environmental conditions, but this comes with higher risk of late spring and early fall frost as well as late droughts Baumgarten *et al.* (2025); Brienen *et al.* (2020). At the opposite side of the spectrum, determinate species are usually long-lived and slow-growth and are mainly constrained by conditions during bud formation, this may increase bud survival at the detriment of opportunistic growth in face of better-than-expected conditions Baumgarten *et al.* (2025) (REF).

Thus primary versus secondary growth allocation, coupled with growth determinacy are variables often overlooked, but which greatly vary across species and that are likely to affect how they species respond to shifting season length.

1.3.4. Getting growth temporal resolution is labor-intensive and expensive (e.g. dendrometer costs) To know when trees start and stop to grow within a single growing season (data not extractable through tree-rings), there are two methods, one being labor intensive (1) and the other being expensive (2).

1. TrepHor is a tool that allows recurrent sampling of mature trees where a 2mm microcore is extracted from the tree a different times during the growing season. By sampling multiple times a single tree, growth temporality can be inferred by counting the ring cell increment between each sample. While this non-destructive tool can be extremely valuable, getting large sample size can hardly be feasible Rossi *et al.* (2006).

2. Dendrometers allow to monitor stem radius variation, measuring irreversible secondary growth, but also stem water fluctuations and thermal expansion, often leading to biased estimates of growth increment temporality Camarero *et al.* (2010).

1.4 Objectives

My objectives for Fuelinex are to assess tree species' potential to prolong or stretch their activity schedule by artificially manipulating growing season length and analyse how this translates (or not) into growth, during the current year (2024) and in the following year (2025). I will also conduct a secondary experiment to examine whether trees can absorb nutrients late in the season and if that translates into growth during the following season. For the CookieSpotters projects, I will investigate how the timing of phenological events affects growth across years for juvenile and mature trees, using observational phenology data and tree ring images.

Together, my two chapters will allow me to address the paradox of the absence of increased growth despite longer growing seasons.

1.5 Research questions

necessary after the objectives? Fuelinex: How do extended growing seasons affect tree growth across different species, both immediately (in the same year as the extended season) and in subsequent years? CookieSpotters: How does phenology regulate tree growth in urban ecosystems?

301 **2 Methods**

302 **2.1 Fuelinex**

303 **2.2 CookieSpotters**

304 **Wildchrokie**

305 1. Common garden from 2015 to 2023

306 2. Four species within the Betulacea family (Table 2)

307 3. Data: phenology, height, tree rings

308 4. Analysis: Hierarchical model to understand how tree ring width relates to GDD

309 **Treespotters**

310

311 1. Citizen science project from 2015 to today (Table 3)

312 2. Tree coring

313 3. Data: phenology, tree rings

314 4. Analysis: Hierarchical model to understand how tree ring width relates to GDD

315 **3.1. Spring frosts**

Mechanisms	Early warm spells → early leaf out → hard frost (<-2Celsius) → tissue death = loss of photosynthetic capacity Polgar & Primack (2011); Response: second cohort of leaves are more efficient and mitigate carbon sequestration loss Reinmann <i>et al.</i> (2023)
Global trend of occurrence	Most vulnerable regions are the ones with no past risk of occurrence (); ↑ in Europe and East Asia, but ↓ North America; Global trend is controversial Reinmann <i>et al.</i> (2023)
Consequences (Individual and Ecosystem level consequences)	Loss of vegetative tissue = ↓ photosynthesis = ↓ and remobilization of NSC to repair damaged tissues = ↓ secondary growth (Meyer24); Loss of reproductive tissue (higher flower mortality) (Sgubin2018The risk); Costs for orchards and stuff Reinmann <i>et al.</i> (2023)
Differences across species/provenance	

Table 1: Fuelinex species grouped by tree type, life history, and wood anatomy.

Deciduous Trees			
Common Name (Latin)	Life History Strategy	Wood Anatomy	n (ap- prox)
Bur oak (<i>Quercus macrocarpa</i>)	Slow-growth, long life	Ring-porous	87
Bitter cherry (<i>Prunus virginiana</i>)	Fast-growth, short life	Diffuse-porous	78
Box elder (<i>Acer negundo</i>)	Fast-growth, short life	Diffuse-porous	90
Balsam poplar (<i>Populus balsamifera</i>)	Fast-growth, short life	Diffuse-porous	84
Paper birch (<i>Betula papyrifera</i>)	Fast-growth, short life	Diffuse-porous	90
Evergreen Trees			
White pine (<i>Pinus strobus</i>)	Slow-growth, long life	Non-porous	89
Giant Sequoia (<i>Sequoiadendron giganteum</i>)	Slow-growth, long life	Non-porous	54

Table 2: Wilchrokic species grouped by tree type, life history, and wood anatomy.

Deciduous Trees			
Common Name (Latin)	Life History Strategy	Wood Anatomy	n
Paper birch (<i>Betula papyrifera</i>)	Fast-growth, short life	Diffuse-porous	8
Yellow birch (<i>Betula alleghaniensis</i>)	Moderate-growth, moderate life	Diffuse-porous	21
Grey birch (<i>Betula populifolia</i>)	Fast-growth, short life	Diffuse-porous	29
Grey alder (<i>Alnus incana</i>)	Fast-growth, short life	Diffuse-porous	31

Table 3: Treespotters species grouped by tree type, life history, and wood anatomy.

Deciduous Trees			
Common Name (Latin)	Life History Strategy	Wood Anatomy	n
American basswood (<i>Tilia americana</i>)	Fast-growth, moderate life	Diffuse-porous	5
Eastern cottonwood (<i>Populus deltoides</i>)	Fast-growth, short life	Diffuse-porous	4
Northern red oak (<i>Quercus rubra</i>)	Moderate-growth, long life	Ring-porous	4
White oak (<i>Quercus alba</i>)	Slow-growth, long life	Ring-porous	5
Pignut hickory (<i>Carya glabra</i>)	Slow-growth, long life	Ring-porous	4
Shagbark hickory (<i>Carya ovata</i>)	Slow-growth, long life	Ring-porous	4
River birch (<i>Betula nigra</i>)	Fast-growth, short life	Diffuse-porous	5
Yellow birch (<i>Betula alleghaniensis</i>)	Moderate-growth, moderate life	Diffuse-porous	4
Sugar maple (<i>Acer saccharum</i>)	Slow-growth, long life	Diffuse-porous	5
Red maple (<i>Acer rubrum</i>)	Slow-growth, long life	Diffuse-porous	4
Yellow buckeye (<i>Aesculus flava</i>)	Moderate-growth, moderate life	Diffuse-porous	5

3.2. Drought

Mechanisms	<ul style="list-style-type: none"> — Hot temperature + low precipitation (aka global-change-type drought Tyree & Zimmermann (2002)) = ↑ evapotranspiration → less water in soil → cavitation → embolism → hydraulic failure Tyree & Zimmermann (2002) = tissue death Choat <i>et al.</i> (2018); — Earlier spring phenology = longer GS → increases vegetative growth → increases evapotranspiration → increases drawdown of soil moisture = progressive water stress Li <i>et al.</i> (2023) — Long-term vs short-term stomatal responses and consequences on tissue death Choat <i>et al.</i> (2018); — Recovery and its determinants Choat <i>et al.</i> (2018); Li <i>et al.</i> (2023)
Global trend of occurrence	<ul style="list-style-type: none"> — ↑ precipitation anomalies since 1990 Trenberth <i>et al.</i> (2014); — Models often exclude PDO/ENSO which limit the capacity to attribute increasing droughts to CC Trenberth <i>et al.</i> (2014); — Weak evidence of detection and attribution of changes in meteorological drought since the mid-20th century Change (2014); — Using a spacial, model-based perspective, anthropogenic forcing increased the frequency, duration and intensity of SPI-based droughts for Americas, Mediterranean, W/S Africa and E Asia Chiang <i>et al.</i> (2021) (Marvel2019Twentieth; Hidalgo2009Detection)
Consequences (Individual and Ecosystem level consequences)	<ul style="list-style-type: none"> — Recurring droughts may limit trees' ability to recover from other types of stress. — Tree mortality (e.g. Texas and California extreme droughts are estimated to have killed 300 and 102 million trees Li <i>et al.</i> (2023))
Differences across species/provenance	

3.3. Heat waves

	Definition: Heat wave is a period of excessively hot weather (5 or more consecutive days of prolonged heat in which the daily maximum temperature is higher than the average maximum temperature by 5 °C), which may be accompanied by high humidity Marx <i>et al.</i> (2021).
321	Mechanisms ↑ atmospheric CO ₂ = ↑ temperature → ↑ heat waves... More specifically: A mechanism for the increase occurrence of heat waves is a weakening of the polar jet stream (important weather factor for middle latitude regions of North America, Europe and Asia) caused by global warming which increases the occurrence of stationary weather, resulting in heavy rain falls or heat waves Marx <i>et al.</i> (2021). Extreme heat → growth either through (1) Directly via cell processes disruption or (2) indirectly via effects of rising leaf-to-air vapor deficit (VPD) Gagne <i>et al.</i> (2020). Increased temperature leads to reduced photosynthesis which can be attributed to: 1. Damage to photosynthetic machinery 2. Inactivation of RUBISCO 3. Reduction to RuBP regeneration 4. Membrane stability 5. Increased mitochondrial respiration and photorespiration (Hauck2025Heat)
322	Global trend of occurrence Heat waves have increased Gagne <i>et al.</i> (2020); Meehl & Tebaldi (2004); Teskey <i>et al.</i> (2015) and are expected to increase under future climate change Dosio <i>et al.</i> (2018); Change (2014); Teskey <i>et al.</i> (2015). Summertime extreme temperatures associated with prolonged heat waves, lasting for several weeks, now impact approximately 10% of land surfaces, up from only 1% in the 1960s. Teskey <i>et al.</i> (2015). The more intense and more frequently occurring heat waves cannot be explained solely by natural climate variations and without human-made climate change Marx <i>et al.</i> (2021).
323	Consequences (Individual and Ecosystem level consequences) - Reduced photosynthesis - Increased mortality - Photosynthetic tissue loss Gagne <i>et al.</i> (2020).
324	Differences across species/provenance Some species have thermal photosynthetic/respiratory acclimation while others don't. Growth and survival will change depending on species to thermally acclimate to both photosynthesis and respiration - This is explained by growth strategies of gymnosperms vs angiosperms (which are usually better)
